ABSTRACT

This research aims to investigate the possibilities of alternative non-conventional specimens for friction calibration. From literature survey it is observed that researchers have made attempts to investigate alternate specimens for friction calibration. It is found that ring compression test is recommended as the standard test for determination of coefficient of friction, because it gives reliable results. There is need to search other friction of friction calibration specimens, which are in same conformity as ring compression test. Two different solid geometry specimens are tried for friction prediction using computer simulation techniques. Finite Element analyses of the compression test are carried out in order to study the deformation behaviour with respect to friction. Based on the deformation studies, correlation has been made between diameter ratios and friction. The deformed radii at various locations for different friction conditions are recorded and it can be observed, that there is continuous decrease in end radius with respect to friction. Friction calibration curves for these specimens are generated. In order to validate the predictability of these specimens, real experiments on them are carried out. Rings of standard dimensional ratio 6:3:1 in the same machine. Friction predictions from both specimen are found to be in close match, proposed alternate specimen offers a powerful tool for friction prediction in the absence of ring specimen.

Key-words: Forming; Friction Calibration Curve; Ring compression; Non-Convention Specimen

I. INTRODUCTION

Metal forming processes involve changing the shape of the work piece by forcing it to flow through a die. Forming can be defined as a process in which desired size and shape is obtained through the plastic deformation of a material. This requires immediate contact between the die (tool) and the work piece. In general, the work piece and the die move relative to each other under pressure or deforming force, which is normal to the die/work piece interface. As a result of this contact, tangential forces are generated at the interface of the die/work piece to resist the relative movement. In order to analyze forming processes, the metal flow, the friction at the die/work piece interface and formability of material have to be described for a given process. For example the coefficient of friction in cold forming is generally of the under of 0.1, whereas that in hot forming can be as high as 0.6.

Low friction (good lubrication)

High friction (poor lubrication)

II. ROLE OF COMPUTER SIMULATION IN METAL FORMING

In metal forming, a piece of material is plastically deformed between tools to obtain the desired product. Before the digital revolution, only a few analytical tools were available to judge the manufacturing feasibility. Today, computer-based metal forming simulation tools enable the validation of the tool and machine designs for production and an estimate of the final work-piece properties to be expected. The manner in which the material is worked directly determines the final product quality. Kaguchi Shin et al. (2000) demonstrated a method to measure the reduction in height and change in external diameter of ring specimen by testing machine automatically during compressing. Sofuoglu et al. (2001) developed an alternative method to the ring compression test in order to quantitatively evaluate the coefficient of friction, \( m \); at the die/work piece interface. This technique relates the percentage deformation in height of the specimen to the percentage increase in extruded height of the specimen. Sahin et al. (2005) proposed a new approach to investigate the effect of the surface roughness on the frictional properties for different materials and conditions. Three types of steel, commercially pure aluminum, and annealed CuZn40Pb2 brass were used as the test materials in the experimental part of the study. Experimental results were placed into ring compression calibration curves for each of the material type and surface conditions. Rudkins et al. (1996) performed experimental investigation into friction under hot forming conditions using the ring compression test. Finite-element simulations of the ring compression test were also completed under similar temperatures as in the experiments. The correlation between the experimental measurements and the results of the process modeling is presented in the paper. The analysis had been carried out for different values of friction factor \( \mu \) between the die and the specimen and for different values of initial height to diameter (H/D) ratio of the specimen and curves have been plotted for the ratio of spike height to initial height of the billet against the ratio of die displacement to initial height of the billet. Kakkeri et al. (2007) analyzed the metal forming processes and found that a realistic frictional condition must be specified at the die/work piece interface in order to obtain accurate metal flow. They evaluated the coefficient of friction for Al 6061 and Al 6063. Sofuoglu et al. (2000) investigated the effects of material properties, strain-rate sensitivity, and barreling on the behavior of friction calibration curves. A series of ring compression tests were conducted in order to determine the magnitude of the friction coefficient, \( m \), as well as the corresponding calibration curves for two types of modeling materials, white and black plasticine. The experiments were first conducted using the Physical Modeling Technique (PMT) and then simulated via an elastic–plastic finite element code (ABAQUS). Robinson et al. (2004) studied the ring compression test using physical modelling experiments and finite element (FE) simulation. Using commercially available modelling clay, material stress–strain relationships were obtained from compression tests of solid cylindrical specimens. A series of ring compression tests were carried out to obtain friction coefficients for a number of lubricants including Vaseline, zinc stearate and talcum powder. FE simulations were used to derive the friction calibration curves and to evaluate material deformation, geometric changes and load–displacement results. Further investigation is necessary to determine the effects of material properties, test conditions and use of calibration curves on the ring compression test. Rao K.P. et al. (1993) this paper presents a review of the calibration curves developed by various researchers, and discusses their usefulness and limitations for quantitative evaluation.
of friction and flow stress. The experimental data obtained for some aluminium alloys is used for comparing the validity of the calibration curves. A calibration using a bulge parameter based on the maximum diameter and minimum diameter of the bulge is then developed as a function of the interface friction factor. Hayhurst et al. (2004) proposed a new technique to calibrate the model, which utilizes two test piece geometries, namely the solid cylindrical compression test piece and the ring compression test piece. The geometrical changes of all test pieces, carefully measured throughout the tests, for a range of four different friction conditions, dry friction, lubricant, lead metal and nylon, have been predicted with good accuracy using the true stress–true strain constitutive models, the two-parameter friction model, and the finite-element analysis procedures. Wang, W et al. (1996) developed a new test to incorporating a smooth increase of wrap angle during deformation, even at high deformation rates, thus replicating typical condition die radii. Bugini A. et al (1993) in this study FEM calibration chart for ring upsetting at room temperature is drawn when dealing with annealed Aluminium specimens of different height. The method allows the evaluation of the friction coefficient affecting the plastic flow when Teflon films are interposed between dies and specimens. Lee Chorn-Der et al. (2001) developed a method to find the friction factor of the die/work piece interface for the forging process without the need for measurement of the shape changes of the work piece. B. Buchner et al.(2008) presented an experimental investigation of friction in hot forging of AA6082, which is a standard forging alloy in automotive engineering, mechanical engineering and in naval architecture, by employing a modified ring-on-disc test.. Rao et al. (2008) used cylindrical Al–Cu alloy samples with initial aspect ratios of 1.0 and 1.5 between flat platens in lubricated and dry conditions to predict the metal flow. Micro hardness studies revealed the non-uniform deformation within the specimen. Guerin J.D. et al (1999) in this study The Bay-Wanheim’s generalized friction law, developed to model mixed and thin film lubrication cases, is implemented in an industrial finite element software. Both the axisymmetric and 3D formulations are presented. These developments are validated on the ring compression test and numerical, experimental and analytical results are then compared. Joun M.S. et al (2008) compared and investigated the coulomb friction law and the constant shear friction law in detail using a rigid-plastic finite element with emphasis on their application in bulk metal forming. The ring compression test for two different materials was used to evaluate the two friction laws, and then their effect on metal flow lines and forming loads for various friction sensitive metal forming processes were investigated. It was shown that considerable differences exist between the two friction laws, especially in friction-sensitive metal forming processes.

To the best of our knowledge no attempt has been made to generate friction calibration curve using centre intrude non-conventional specimens of aluminum material and its validation with standard friction calibration curves. Detailed study on how the friction calibration on specimens behave during deformation and what type of deformation taking place on the FE deformed mesh has not been conducted. The deformation on centre intrudes and its dependency on the characteristics of ring compression test has not been crystallized so far. This could be studied in detailed for in depth understanding through finite element simulation and their experimental verification of friction calibration curve using ring compression test.

### III. METAL FORMING FINITE ELEMENT SIMULATION SETUP & EXPERIMENTS

The methodology of this experimental numerical study on investigation of non-conventional friction specimen incorporates following steps:

To obtain the flow curve, tensile test using a commercial aluminum specimen is carried out. An aluminum specimen of gauge length 80 mm, prepared as per ASTM standard, is tested in a Shimadzu make Universal Testing Machine(UTM). The test and tested specimens are shown in . The summary of the results obtained from the tensile test are as follows:

(a) Ultimate Tensile Strength $= 163.81 \text{ N/mm}^2$
(b) Yield strength $= 124.13 \text{ N/mm}^2$
(c) Ultimate strain $= 0.2$
(d) Yield strain $= 0.002$

The engineering stress & strain are converted into their true counterparts using standard relationships (Kalpakjian and Schmid, 2004). Based on these results, material modeling is carried out using the power law equation (Meyers and Chawla, 1997):

$$\sigma = k \varepsilon^n$$

where $k$ is the strength coefficient and $n$ is the hardening exponent. The value of $k$ and $n$ obtained from the tensile test results are 225.4 MPa and 0.095 respectively. These data are used in the finite element (FE) simulations.

Two centre intrude specimens are proposed for friction study. Geometry of the centre intrude specimen I and II are shown in Fig. 3 & 4.

Fig. 5 Prepared Specimen of Center Intrude I
IV. PREPARATION OF RING SPECIMENS

Using the same lathe machine and Aluminum piece two ring specimens are also prepared. The dimensions of the rings are –

(a) Outside Diameter OD = 38 mm  
(b) Inside Diameter ID = 19 mm  
(c) Height H = 6.33 mm  

A typical photograph of ring preparation by Dieter, OD:ID:H ratio is 6:3:1. Thus prepared ring is shown in Fig.6

Results of experimental and simulation studies can be described under following heads:-

![Friction Calibration Curve Centre Intrude I](image)
It can be observed that friction calibration curves predict quite accurate results as compared to the ring compression test. Hence such alternate specimens may play important role in friction determination in absence of ring specimens.
V. CONCLUSION

In this study a search has been made to find alternative specimens for friction calibration using finite element simulation. Two non-conventional specimens were tried for this purpose. It is observed that these two specimens could undergo consistent deformation with respect to varying friction. Friction calibration curve, for these two eligible specimens are generated using simulation results. Actual experiments on these non-conventional specimens were also carried out. A ring of standard dimension is also tested in the same machine. When compared, both specimen gave very close friction value. These non standard specimens can be used as a substitute to ring compression test for friction determination. Hence, friction prediction becomes quite simple using such specimens, especially in the absence of ring specimens.
