ABSTRACT

With the increasing penetration of wind power into electric power grids, energy storage devices will be required to dynamically match the intermittency of wind energy. This paper proposes a novel two-layer constant power control scheme for a wind farm equipped with doubly fed induction generator (DFIG) wind turbines. Each DFIG wind turbine is equipped with a super capacitor energy storage system (ESS) and is controlled by the low-layer wind turbine generator (WTG) controllers and coordinated by a high-layer wind farm supervisory controller (WFSC). The WFSC generates the active power references for the low-layer WTG controllers according to the active power demand from or generation commitment to the grid operator; the low-layer WTG controllers then regulate each DFIG wind turbine to generate the desired amount of active power, where the deviations between the available wind energy input and desired active power output are compensated by the ESS with PI controller. Simulation studies are carried out in MATLAB on a wind farm equipped with 15 DFIG wind turbines to verify the effectiveness of the proposed control scheme.

Index Terms: Constant Power Control (CPC), Doubly Fed Induction Generator (DFIG), PI Control, Energy Storage, Supervisory Controller, Wind Turbine.

I. INTRODUCTION

Wind Turbine generators (WTGs) are usually controlled to generate maximum electrical power from wind under normal wind conditions. However, because of the variations of the wind speed, the generated electrical power of a WTG is usually fluctuated. Currently, wind energy only provides about 1%–2% of the U.S.’s electricity supply. At such a penetration level, it is not necessary to require WTGs to participate in automatic generation control, unit commitment, or frequency regulation. However, it is reasonable to expect that wind power will be capable of becoming a major contributor to the nation’s and world’s electricity supply over the next three decades. For instance, the European Wind Energy Association has set a target to satisfy more than 22% of European electricity demand with wind power by 2030 [1]. In the U.S., according to a report [2] by the Department of Energy, it is feasible to supply 20% of the nation’s electricity from wind by 2030. At such high levels of penetration, it will become necessary to require WTGs to supply a desired amount of active power to participate in automatic generation control or frequency regulation of the grid [3]. However, the intermittency of
wind resources can cause high rates of change (ramps) in power generation [4], which is a critical issue for balancing power systems. Moreover, to optimize the economic performance of power systems with high penetrations of wind power, it would be desired to require WTGs to participate in unit commitment, economic dispatch, or electricity market operation [5]. In practice, short-term wind power prediction [6] is carried out to help WTGs provide these functions. However, even using the state-of-the-art methods, prediction errors are present [5]. Under these conditions, the replacement power is supported by reserves, which, however, can be more expensive than base electricity prices [7]. To enable WTGs to effectively participate in frequency and active power regulation, unit commitment, economic dispatch, and electricity market operation, energy storage devices will be required to dynamically match the intermittency of wind energy. In [8], the authors investigated and compared different feasible electric energy storage technologies for intermittent renewable energy generation, such as wind power. Currently, pumped water and compressed air are the most commonly used energy storage technologies for power grids due to their low capital costs [9]. However, these two technologies are heavily dependent on geographical location with relatively low round-trip efficiency. Compared with their peers, batteries and super capacitors are more efficient, have a quicker response to demand variations, and are easy to develop and ubiquitously deployable. Compared to batteries, super capacitors have a higher power density, higher round-trip efficiency, longer cycle life, and lower capital cost per cycle [10]. Therefore, super capacitors are a good candidate for short-term (i.e., seconds to minutes) energy storage that enables WTGs to provide the function of frequency regulation and effectively participate in unit commitment and electricity market operation. The use of super capacitors [10] or batteries [11]–[13] as energy storage devices for WTGs has been studied by some researchers. However, these studies only focused on control and operation of individual WTGs and did not investigate the issues of WTGs to participate in grid regulation. This paper proposes a novel two-layer constant power control (CPC) scheme for a wind farm equipped with doubly fed induction generator (DFIG) wind turbines [14], where each WTG is equipped with a super capacitor energy storage system (ESS). The CPC consists of a high-layer wind farm supervisory controller (WFSC) and low-layer WTG controllers.

![Configuration of A DFIG Wind Turbine Equipped With a Super Capacitor ESS Connected To a Power Grid](image)

**Fig. 1. Configuration of A DFIG Wind Turbine Equipped With a Super Capacitor ESS Connected To a Power Grid**

The high layer WFSC generates the active power references for the low layer WTG controllers of each DFIG wind turbine according to the active power demand from the grid operator. The low-layer WTG controllers then regulate each DFIG wind turbine to generate the desired amount of active power, where the deviations between
the available wind energy input and desired active power output are compensated by the ESS. Simulation studies are carried out in PSCAD/EMTDC for a wind farm equipped with 15 DFIG wind turbines to verify the effectiveness of the proposed control scheme.

II. DFIG WIND TURBINE WITH ENERGY STORAGE

Fig. 1 shows the basic configuration of a DFIG wind turbine equipped with a super capacitor-based ESS. The low speed wind turbine drives a high-speed DFIG through a gearbox. The DFIG is a wound-rotor induction machine. It is connected to the power grid at both stator and rotor terminals. The stator is directly connected to the grid, while the rotor is fed through a variable-frequency converter, which consists of a rotor-side converter (RSC) and a grid-side converter (GSC) connected back to back through a dc link and usually has a rating of a fraction (25%–30%) of the DFIG nominal power. As a consequence, the WTG can operate with the rotational speed in a range of ±25%–30% around the synchronous speed, and its active and reactive powers can be controlled independently. In this paper, an ESS consisting of a super capacitor bank and a two-quadrant dc/dc converter is connected to the dc link of the DFIG converters. The ESS serves as either a source or a sink of active power and therefore contributes to control the generated active power of the WTG. The value of the capacitance of the super capacitor bank can be determined by

\[ C_{\text{ess}} = \frac{2P_n T}{V_{\text{SC}}^2} \]  

where \( C_{\text{ess}} \) is in farads, \( P_n \) is the rated power of the DFIG in watts, \( V_{\text{SC}} \) is the rated voltage of the super capacitor bank in volts, and \( T \) is the desired time period in seconds that the ESS can supply/store energy at the rated power \( (P_n) \) of the DFIG.

Fig. 2. Overall Vector Control Scheme of the RSC.

The use of an ESS in each WTG rather than a large single central ESS for the entire wind farm is based on two reasons. First, this arrangement has a high reliability because the failure of a single ESS unit does not affect the ESS units in other WTGs. Second, the use of an ESS in each WTG can reinforce the dc bus of the DFIG converters during transients, thereby enhancing the low-voltage ride through capability of the WTG [10].
III. CONTROL OF INDIVIDUAL DFIG WIND TURBINE

The control system of each individual DFIG wind turbine generally consists of two parts: 1) the electrical control of the DFIG and 2) the mechanical control of the wind turbine blade pitch angle [14], [15] and yaw system. Control of the DFIG is achieved by controlling the RSC, the GSC, and the ESS (see Fig. 1). The control objective of the RSC is to regulate the stator-side active power $P_s$ and reactive power $Q_s$ independently. The control objective of the GSC is to maintain the dc-link voltage $V_{dc}$ constant and to regulate the reactive power $Q_g$ that the GSC exchanges with the grid. The control objective of the ESS is to regulate the active power $P_g$ that the GSC exchanges with the grid. In this paper, the mechanical control of the wind turbine blade pitch angle is similar to that in [15].

3.1 Control of the RSC

Fig. 2 shows the overall vector control scheme of the RSC, in which the independent control of the stator active power $P_s$ and reactive power $Q_s$ is achieved by means of rotor current regulation in a stator-flux-oriented synchronously rotating reference frame [16]. Therefore, the overall RSC control scheme consists of two cascaded control loops. The outer control loop regulates the stator active and reactive powers independently, which generates the reference signals $i_{dref}$ and $i_{qref}$ of the $d$- and $q$-axis current components, respectively, for the inner-loop current regulation. The outputs of the two current controllers are compensated by the corresponding cross-coupling terms $v_{dref}$ and $v_{qref}$ [14], respectively, to form the total voltage signals $v_{dref}$ and $v_{qref}$. They are then used by the pulse width modulation (PWM) module to generate the gate control signals to drive the RSC. The reference signals of the outer-loop power controllers are generated by the high-layer WFSC.

3.2 Control of the GSC

Fig. 3 shows the overall vector control scheme of the GSC, in which the control of the dc-link voltage $V_{dc}$ and the reactive power $Q_g$ exchanged between the GSC and the grid is achieved by means of current regulation in a synchronously rotating reference frame [16]. Again, the overall GSC control scheme consists of two cascaded control loops. The outer control loop regulates the dc-link voltage $V_{dc}$ and the reactive power $Q_g$, respectively.
which generates the reference signals $i_{d}^{*}$ and $i_{q}^{*}$ of the $d$- and $q$-axis current components, respectively, for the inner-loop current regulation. The outputs of the two current controllers are compensated by the corresponding cross coupling terms $v_{dg0}$ and $v_{qg0}$ [14], respectively, to form the total voltage signals $v_{d}$ and $v_{q}$. They are then used by the PWM module to generate the gate control signals to drive the GSC. The reference signal of the outer-loop reactive power controller is generated by the high-layer WFSC.

### 3.3 Configuration and Control of the ESS

Fig. 4 shows the configuration and control of the ESS. The ESS consists of a super capacitor bank and a two-quadrant dc/dc converter connected to the dc link of the DFIG. The dc/dc converter contains two insulated-gate bipolar transistor (IGBT) switches $S_1$ and $S_2$. Their duty ratios are controlled to regulate the active power $P_g$ that the GSC exchanges with the grid. In this configuration, the dc/dc converter can operate in two different modes, i.e., buck or boost mode, depending on the status of the two IGBT switches. If $S_1$ is open, the dc/dc converter operates in the boost mode; if $S_2$ is open, the dc/dc converter operates in the buck mode. The duty ratio $D_1$ of $S_1$ in the buck mode can be approximately expressed as

$$D_1 = \frac{V_{dc}}{V_{sc}}$$

(2)

and the duty ratio $D_2$ of $S_2$ in the boost mode is $D_2 = 1 - D_1$. In this paper, the nominal dc voltage ratio $V_{sc,n}/V_{dc,n}$ is 0.5, where $V_{sc,n}$ and $V_{dc,n}$ are the nominal voltages of the super capacitor bank and the DFIG dc link, respectively. Therefore, the nominal duty ratio $D_{1,n}$ of $S_1$ is 0.5.

![Fig. 5 Blade Pitch Control for the Wind Turbine](image)

Fig. 5 Blade Pitch Control for the Wind Turbine

The operating modes and duty ratios $D_1$ and $D_2$ of the dc/dc converter are controlled depending on the relationship between the active powers $P_r$ of the RSC and $P_g$ of the GSC. If $P_r$ is greater than $P_g$, the converter is in buck mode and $D_1$ is controlled, such that the super capacitor bank serves as a sink to absorb active power, which results in the increase of its voltage $V_{sc}$. On the contrary, if $P_g$ is greater than $P_r$, the converter is in boost mode and $D_2$ is controlled, such that the super capacitor bank serves as a source to supply active power, which results in the decrease of its voltage $V_{sc}$. Therefore, by controlling the operating modes and duty ratios of the dc/dc converter, the ESS serves as either a source or a sink of active power to control the generated active power of the WTG. In Fig. 4, the reference signal $P_{r+g}$ is generated by the high-layer WFSC.

### 3.4 Wind Turbine Blade Pitch Control

Fig. 5 shows the blade pitch control for the wind turbine, where $\omega_r$ and $P_e (= P_r + P_g)$ are the rotating speed and output active power of the DFIG, respectively. When the wind speed is below the rated value and the WTG is
required to generate the maximum power, \( \omega_r \) and \( P_e \) are set at their reference values, and the blade pitch control is deactivated. When the wind speed is below the rated value, but the WTG is required to generate a constant power less than the maximum power, the active power controller may be activated, where the reference signal \( P_{e*} \) is generated by the high-layer WFSC and \( P_e \) takes the actual measured value. The active power controller adjusts the blade pitch angle to reduce the mechanical power that the turbine extracts from wind. This reduces the imbalance between the turbine mechanical power and the DFIG output active power, thereby reducing the mechanical stress in the WTG and stabilizing the WTG system. Finally, when the wind speed increases above the rated value, both \( \omega_r \) and \( P_e \) take the actual measured values, and both the speed and active power controllers are activated to adjust the blade pitch angle.

\[
\omega_{\text{opt}} = k(\beta) v_{\text{ref}}
\]

(3)

where \( k \) is a constant at a certain value of \( \beta \). Then, the maximum mechanical power \( P_{\text{me},\text{max}} \) that the wind turbine extracts from the wind can be calculated by the well-known wind turbine aerodynamic characteristics

\[
P_{\text{me},\text{max}} = \frac{1}{2} \rho_i A_r \omega_i^3 C_{\text{Pi}}(\lambda_i, \beta_i)
\]

(4)

where \( \rho_i \) is the air density in kilograms per cubic meter; \( A_r = \pi R^2 \) is the area in square meters swept by the rotor blades with \( R \) being the blade length in meters; and \( C_{\text{Pi}} \) is the power coefficient, which is a function of both tip-speed ratio \( \lambda_i \) and the blade pitch angle \( \beta_i \), where \( \lambda_i \) is defined by

\[
\lambda_i = \frac{\omega_i R}{v_{\text{ref}}}
\]

(5)

Fig. 6 Proposed Two-Layer CPC Scheme for the Wind Farm.

As shown in Fig. 6, once \( P_{\text{ess},\text{max}} \) of each WTG is determined, the total maximum power \( P_{\text{ess},\text{max}} \) that can be exchanged between the supercapacitor bank and the DFIG dc link of all WTGs can be determined by

\[
P_{\text{ess},\text{max}} = \sum_{i=1}^{N} P_{\text{ess},\text{max}}
\]

(18)

Finally, depending on the relationship of \( P_{\text{ess},d} \) and \( P_{\text{ess},\text{max}} \), the reference signals \( P_{e*\text{si}} \) (see Fig. 2) and \( P_{e*\text{gi}} \) (see Fig. 4) of each WTG can be determined. Specifically, if \( |P_{\text{ess},d}| \leq |P_{\text{ess},\text{max}}| \), \( P_{e*\text{si}} \) and \( P_{e*\text{gi}} \) can be determined directly, as shown in Fig. 6, where the partition coefficients \( a_i \)'s are calculated by

\[
a_i = \frac{P_{\text{ess},\text{max}}}{P_{e*\text{max}} - P_{e*\text{max}}}
\]

(19)
IV. SIMULATION RESULTS

Simulation studies are carried out for a wind farm with DFIG wind turbines (see Fig. 7) to verify the effectiveness of the proposed control scheme under various operating conditions. Each DFIG wind turbine (see Fig. 1) has a 3.6-MW power capacity [14], [15]. The total power capacity of the wind farm is 54 MW. Each DFIG wind turbine is connected to the internal network of the wind farm through a 4.16/34.5-kV voltage step-up transformer. The high-voltage terminals of all transformers in the wind farm are connected by 34.5-kV power cables to form the internal network of the wind farm. In this paper, the power grid is represented by an infinite source. The ESS of each WTG is designed to continuously supply/store 20% of the DFIG rated power for approximately 60 s. Then, the total capacitance of the super capacitor bank can be obtained from (1). The parameters of the WTG, the ESS, and the power network are listed in the Appendix. Some typical results are shown and discussed in this section.

V CONCLUSION

This paper has proposed a novel two-layer CPC scheme for a wind farm equipped with DFIG wind turbines. Each wind turbine is equipped with a super capacitor-based ESS with PI controller, which is connected to the dc link of the DFIG through a two-quadrant dc/dc converter. The ESS serves as either a source or a sink of active power to control the generated active power of the DFIG wind turbine with PI. Each individual DFIG wind turbine and its ESS are controlled by low-layer WTG controllers, which are coordinated by a high-layer WFSC to generate constant active power as required by or committed to the grid operator. Simulation studies have been carried out for a wind farm equipped with 15 DFIG wind turbines to verify the effectiveness of the proposed CPC scheme. Results have shown that the proposed CPC scheme enabled the wind farm to effectively participate in unit commitment and active power and frequency regulations of the grid with PI controller. The proposed system and control scheme provides a solution to help achieve high levels of penetration of wind power into electric power grids.
